Markov Decision Processes

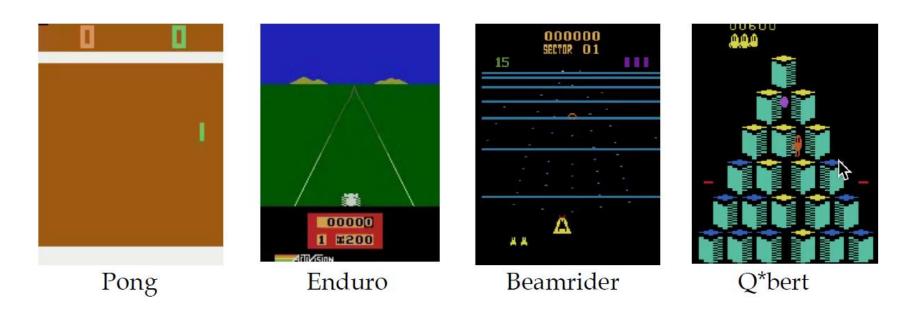

Overcoming Resource Limits with Randomization

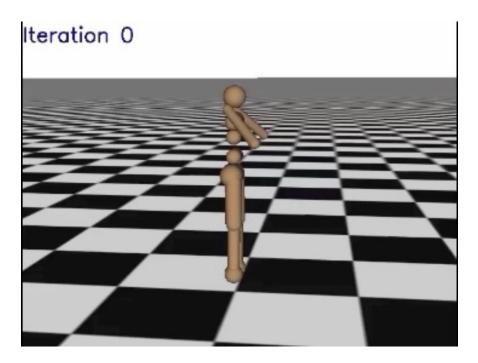

- Today: value iteration and policy iteration
 - Assumes we can query model of the world
- Next: learning from trial and error
 - Learn only from interactions with the world

Non-Deterministic Search

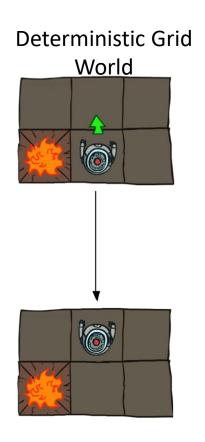

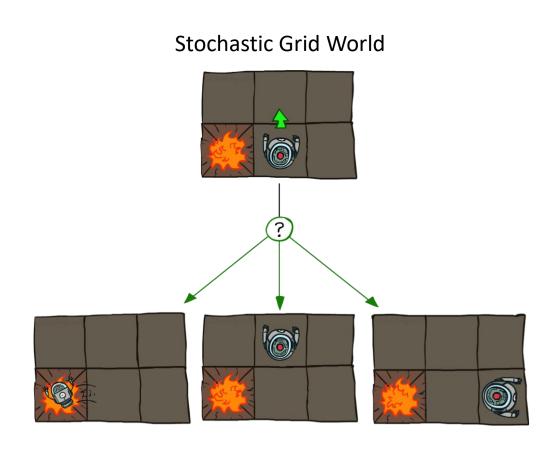

Example: Grid World

- A maze-like problem
 - The agent lives in a grid
 - Walls block the agent's path
- Noisy movement: actions do not always go as planned
 - 80% of the time, the action North takes the agent North (if there is no wall there)
 - 10% of the time, North takes the agent West; 10%
 East
 - If there is a wall in the direction the agent would have been taken, the agent stays put
- The agent receives rewards each time step
 - Small "living" reward each step (can be negative)
 - Big rewards come at the end (good or bad)
- Goal: maximize sum of rewards

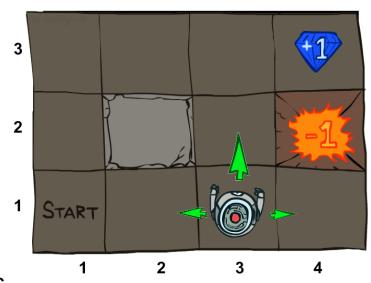

Grid World Actions

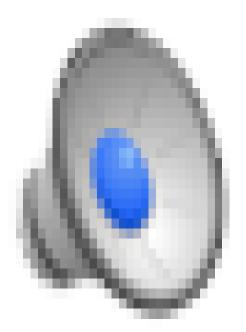

Markov Decision Processes

- An MDP is defined by:
 - □ A set of states s ∈ S
 - A set of actions a ∈ A
 - A transition function T(s, a, s')
 - Probability that a from s leads to s', i.e., P(s'| s, a)
 - Also called the model or the dynamics
 - A reward function R(s, a, s')
 - Sometimes just R(s) or R(s')
 - A start state
 - Maybe a terminal state
- MDPs are non-deterministic search problems
 - One way to solve them is with expectimax search
 - We'll have a new tool soon

Video of Demo Gridworld Manual Intro

What is Markov about MDPs?

- "Markov" generally means that given the present state, the future and the past are independent
- For Markov decision processes, "Markov" means action outcomes depend only on the current state

$$P(S_{t+1} = s' | S_t = s_t, A_t = a_t, S_{t-1} = s_{t-1}, A_{t-1}, \dots S_0 = s_0)$$
=

$$P(S_{t+1} = s' | S_t = s_t, A_t = a_t)$$

 This is just like search, where the successor function could only depend on the current state (not the history)

Andrey Markov (1856-1922)

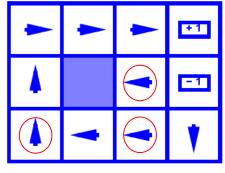

Policies

- In deterministic single-agent search problems, we wanted an optimal plan, or sequence of actions, from start to a goal
- For MDPs, we want an optimal policy π*: S → A
 - \Box A policy π gives an action for each state
 - An optimal policy is one that maximizes expected utility if followed
 - An explicit policy defines a reflex agent
- Expectimax didn't compute entire policies
 - It computed the action for a single state only

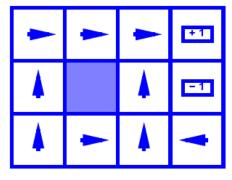

Optimal policy when R(s, a, s') = -0.03for all non-terminals s

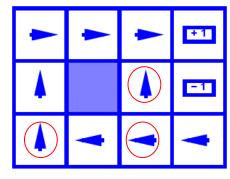

Optimal Policies

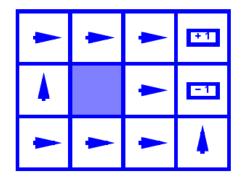

R(s) = -0.01

$$R(s) = -0.4$$

R(s) = -0.03

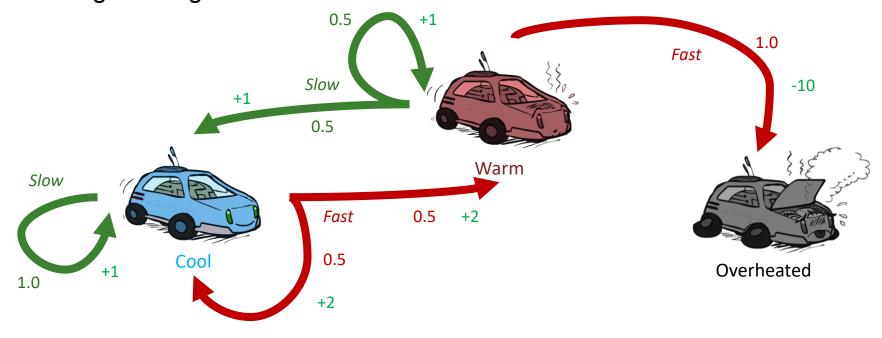

R(s) = -2.0

Example: Racing

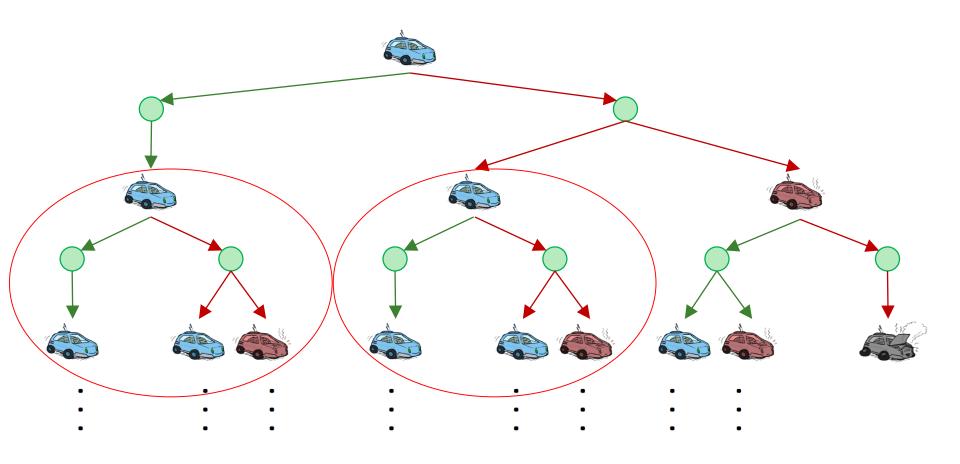

Example: Racing

- A robot car wants to travel far, quickly
- Three states: Cool, Warm, Overheated
- Two actions: Slow, Fast
- Going faster gets double reward

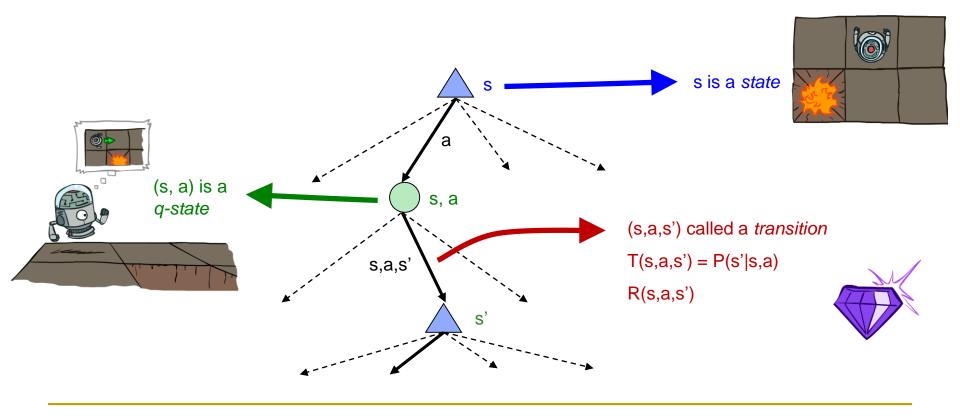

Racing Search Tree

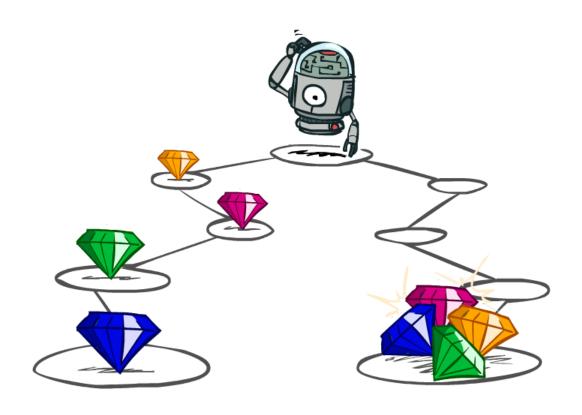

MDP Search Trees

Each MDP state projects an Expectimax-like search tree

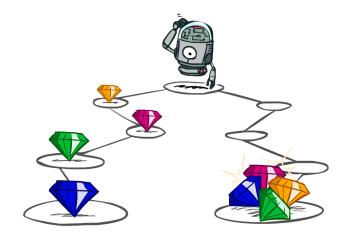

Utilities of Sequences

Utilities of Sequences

- What preferences should an agent have over reward sequences?
- More or less?

Now or later?

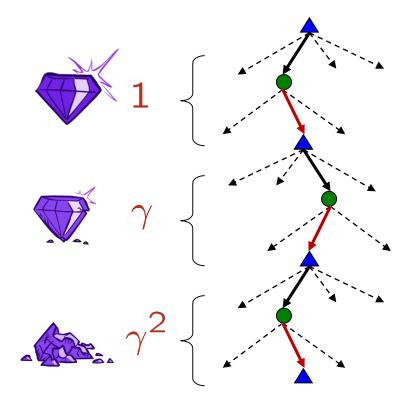

Discounting

- It's reasonable to maximize the sum of rewards
- It's also reasonable to prefer rewards now to rewards later
- One solution: values of rewards decay exponentially

Discounting

- How to discount?
 - Each time we descend a level, we multiply in the discount once
- Why discount?
 - Sooner rewards probably do have higher utility than later rewards
 - Also helps our algorithms converge
- Example: discount of 0.5
 - \cup U([1,2,3]) = 1*1 + 0.5*2 + 0.25*3
 - \cup U([1,2,3]) < U([3,2,1])

Discounting in Public Policy

Council of Economic Advisers Issue Brief January 2017

DISCOUNTING FOR PUBLIC POLICY: THEORY AND RECENT EVIDENCE ON THE MERITS OF UPDATING THE DISCOUNT RATE

Weighing benefits and costs that take place over time requires discounting those amounts to present value equivalents. This necessitates selecting a discount rate which can adjust for the fact that resources are more valuable today than in the future if consumers prefer to consume today rather than wait, or if firms could be earning a positive return on invested resources. Current guidance from the office of management and budget requires using both a 7 percent and 3 percent real discount rate in regulatory benefit-cost analyses. This issue brief reassesses the current choice of discount rates and methodologies for selecting the 3 percent and 7 percent rates. Empirical evidence suggests that real interest rates around the world have come down since the last evaluation of the rates, and new theoretical advances considering future uncertainty likely suggest lower long term rates, as well. In general the evidence supports lowering these discount rates, with a plausible best guess based on the available information being that the lower discount rate should be at most 2 percent while the upper discount rate should also likely be reduced.

 $\gamma = 0.93$ or

0.97

obamawhitehouse.archives.gov/sites/default/files/page/files/201701_cea_discounting_issue_brief.pdf

Quiz: Discounting

Given:

- Actions: East, West, and Exit (only available in exit states a, e)
- Transitions: deterministic
- Quiz 1: For $\gamma = 1$, what is the optimal policy?

10				1
----	--	--	--	---

• Quiz 2: For γ = 0.1, what is the optimal policy?

)	10				1
---	----	--	--	--	---

Quiz 3: For which γ are West and East equally good when in state d?

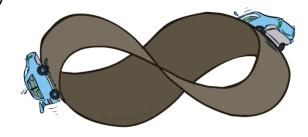

Infinite Utilities?!

 Problem: What if the game lasts forever? Do we get infinite rewards?

Solutions:

- Finite horizon: (similar to depth-limited search)
 - Terminate episodes after a fixed T steps (e.g. life)
 - Gives nonstationary policies (π depends on time left)

Infinite Utilities?!

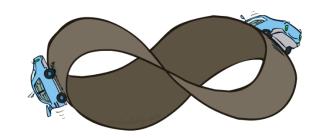

- Problem: What if the game lasts forever? Do we get infinite rewards?
- Solutions:
 - Finite horizon: (similar to depth-limited search)
 - Terminate episodes after a fixed T steps (e.g. life)
 - Gives nonstationary policies (π depends on time left)
 - Discounting: use $0 < \gamma < 1$

$$U([r_0, \dots r_\infty]) = \sum_{t=0}^{\infty} \gamma^t r_t \le R_{\text{max}}/(1-\gamma)$$

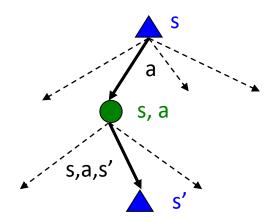

Smaller γ means smaller "horizon" – shorter term focus

Absorbing state: guarantee that for every policy, a terminal state will eventually be reached (like "overheated" for racing)

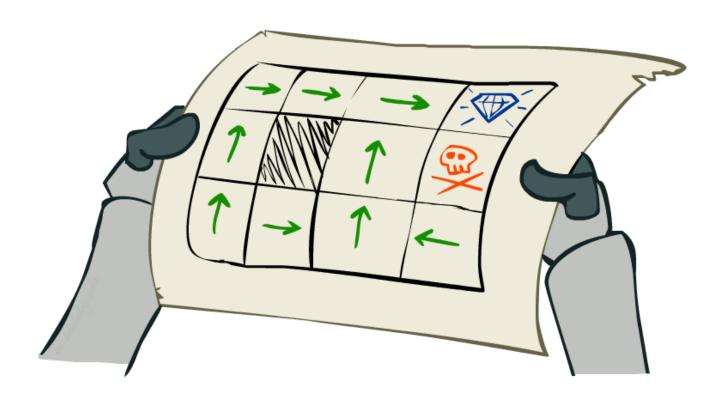

Recap: Defining MDPs

- Markov decision processes:
 - Set of states S
 - □ Start state s₀
 - Set of actions A
 - □ Transitions P(s'|s,a) (or T(s,a,s'))
 - Rewards R(s,a,s') (and discount γ)
- MDP quantities so far:
 - Policy = Choice of action for each state
 - Utility = sum of (discounted) rewards

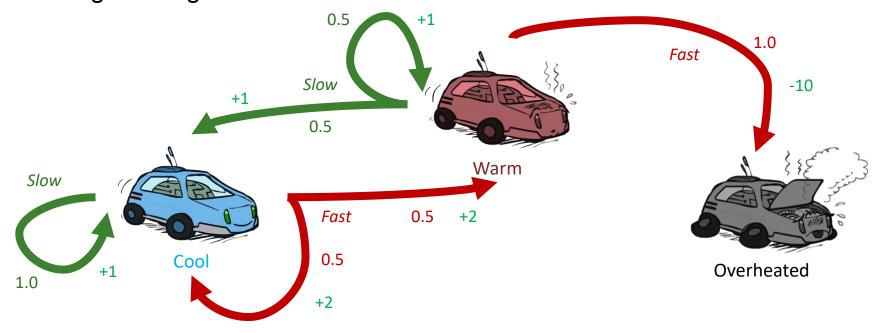

Solving MDPs

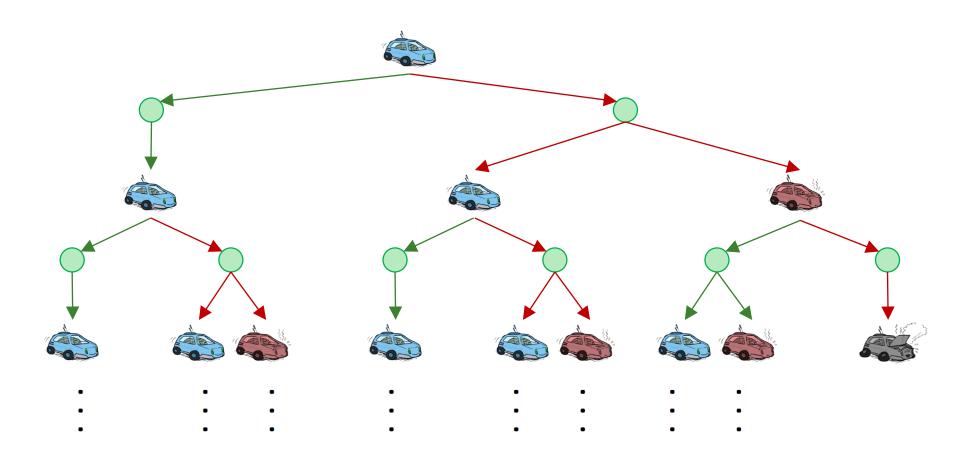

Recall: Racing

- A robot car wants to travel far, quickly
- Three states: Cool, Warm, Overheated
- Two actions: *Slow*, *Fast*
- Going faster gets double reward

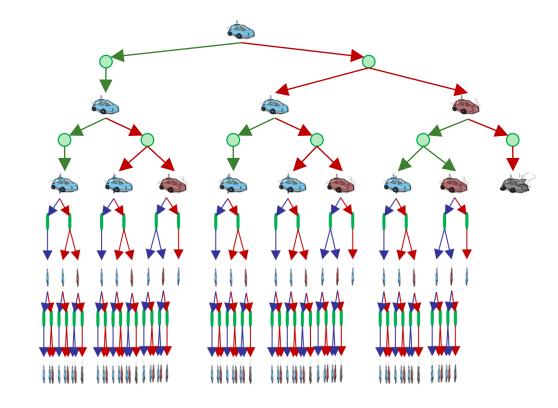

Racing Search Tree

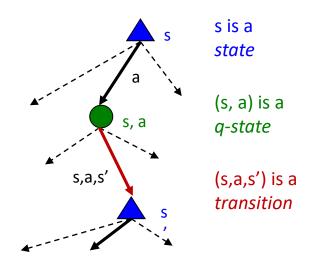

Racing Search Tree

- We're doing way too much work with Expectimax!
- Problem: States are repeated
 - Idea: Only compute needed quantities once
- Problem: Tree goes on forever
 - Idea: Do a depth-limited computation, but with increasing depths until change is small
 - Note: deep parts of the tree eventually don't matter if γ < 1

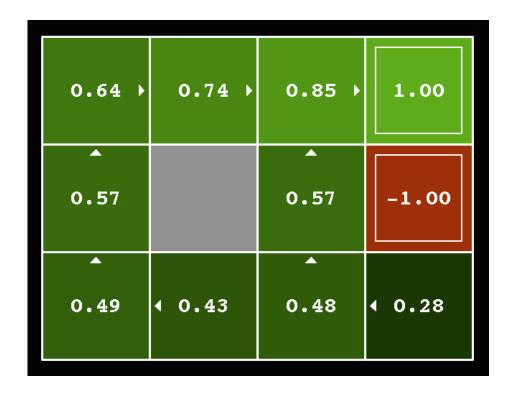

Optimal Quantities

- The value (utility) of a state s:
 - V*(s) = expected utility starting in s and acting optimally
- The value (utility) of a q-state (s,a):
 - Q*(s,a) = expected utility starting out having taken action a from state s and (thereafter) acting optimally
- The optimal policy:
 - $\neg \pi^*(s) = optimal action from state s$

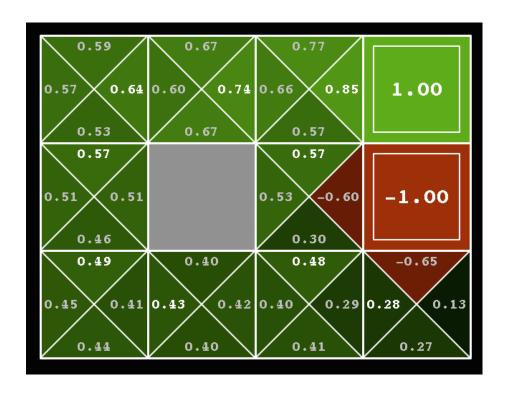

Snapshot of Demo – Gridworld V* Values

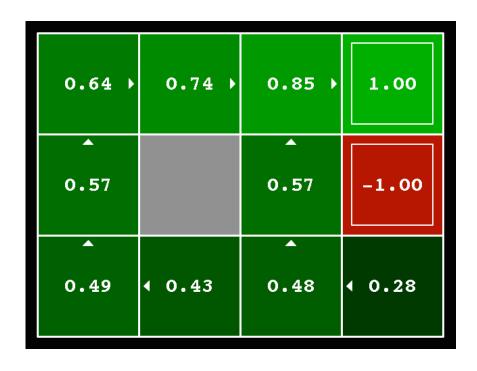

Noise = 0.2 Discount = 0.9 Living reward = 0

Snapshot of Demo – Gridworld Q* Values

Snapshot of Demo – Gridworld π^* Values

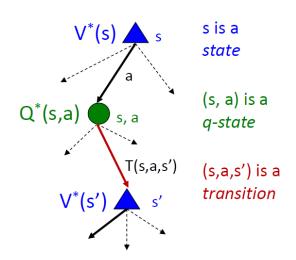

Values of States

Recursive definition of value (similar to Expectimax):

$$V^{*}(s) = \max_{a} Q^{*}(s, a)$$

$$Q^{*}(s, a) = \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V^{*}(s') \right]$$

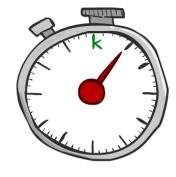

$$V^{*}(s) = \max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V^{*}(s') \right]$$

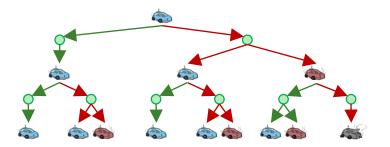

But how do we solve these equations?

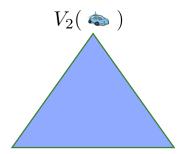

Time-Limited Values

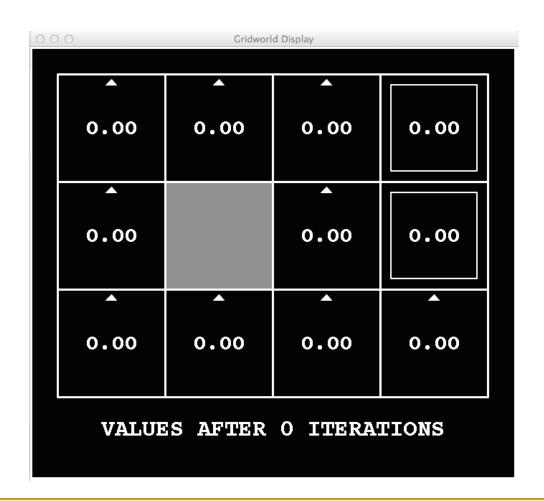

- Key idea: time-limited values
- Define V_k(s) to be the optimal value of s
 if the game ends in k more time steps
 - Equivalently, it's what a depth-k Expectimax would give from s

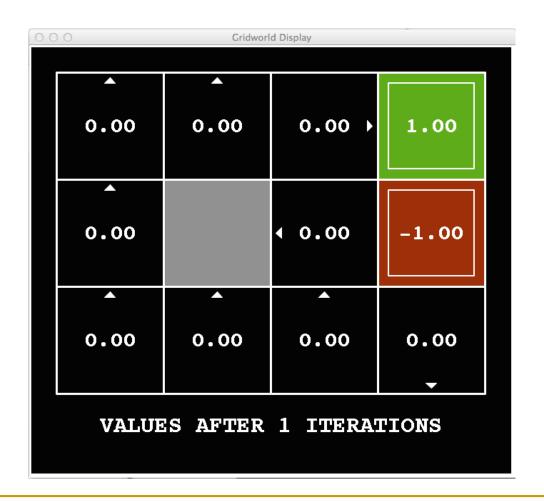

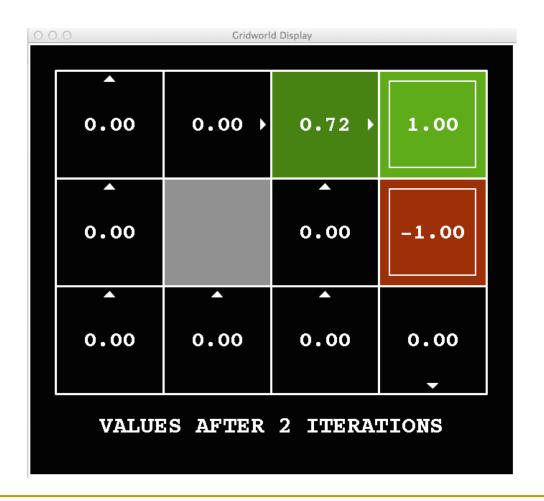

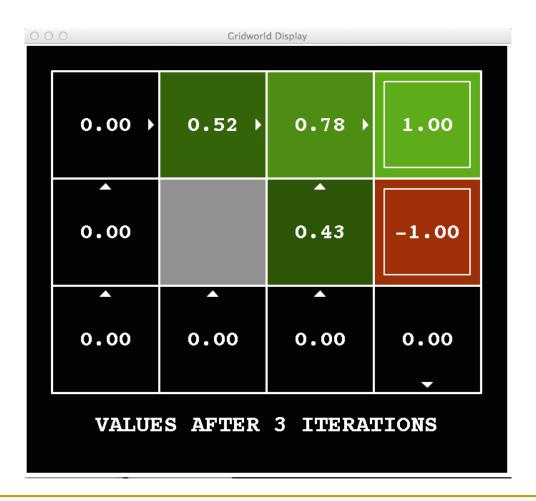

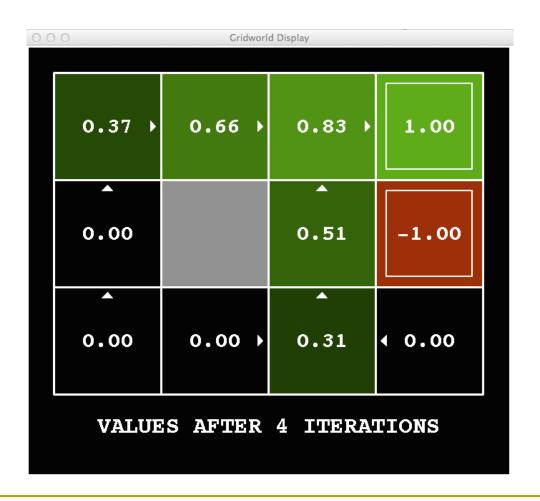

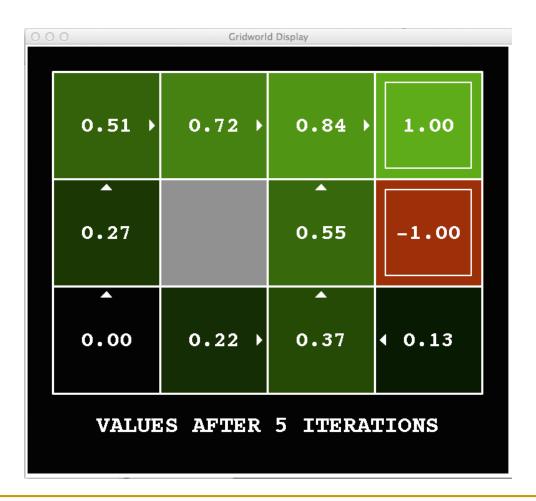

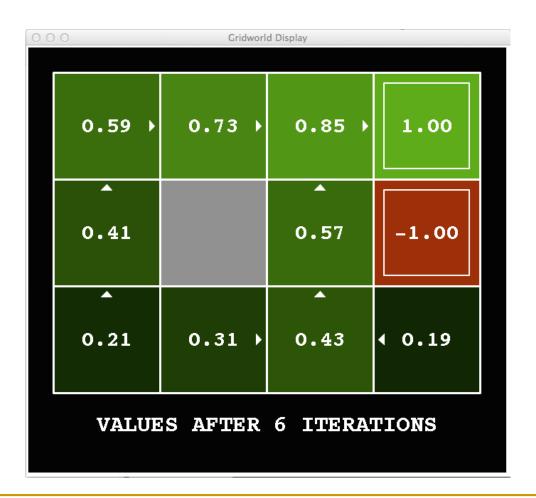

Noise = 0.2 Discount = 0.9 Living reward = 0

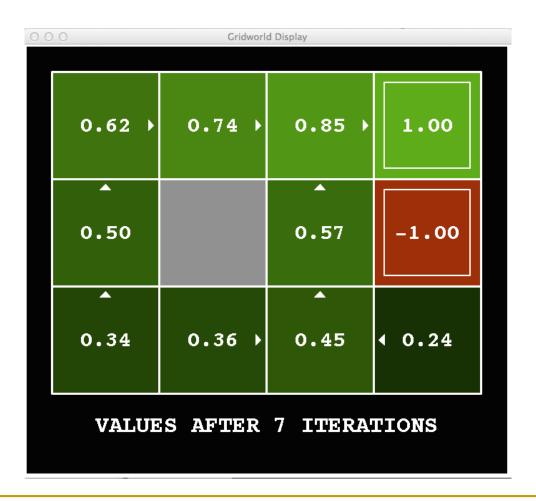

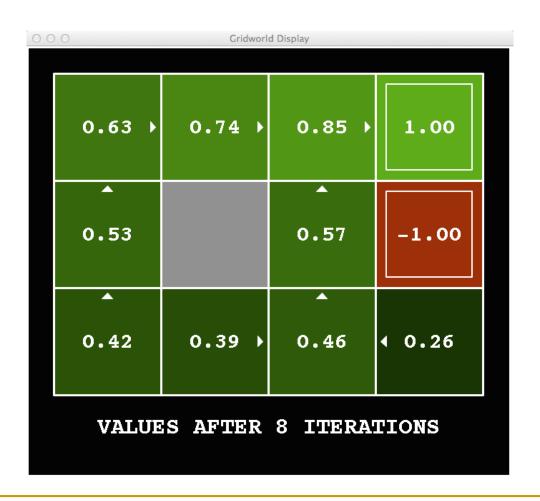

Noise = 0.2 Discount = 0.9 Living reward = 0

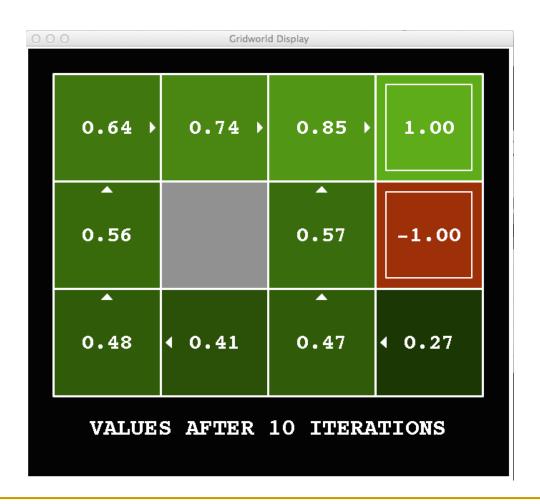

Noise = 0.2 Discount = 0.9 Living reward = 0

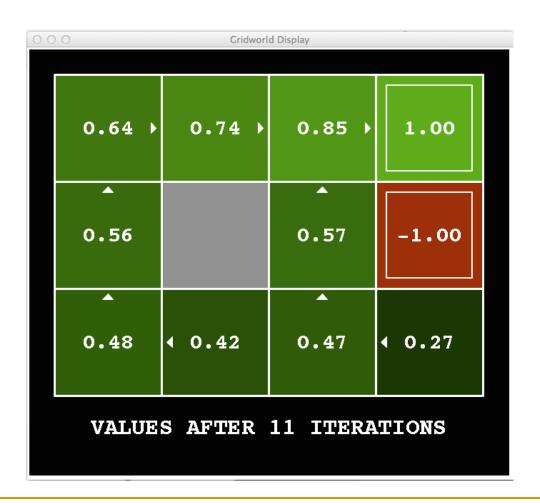

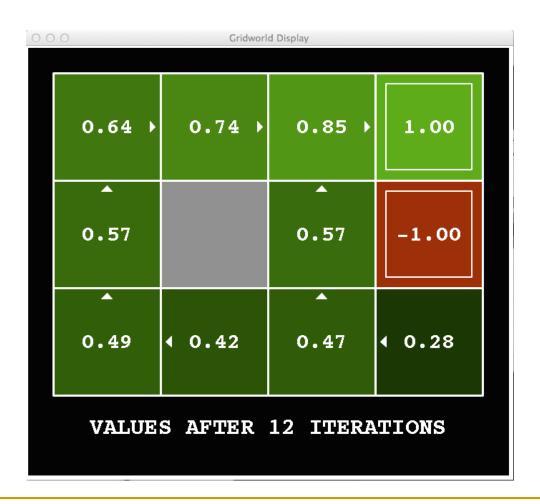

Noise = 0.2 Discount = 0.9 Living reward = 0

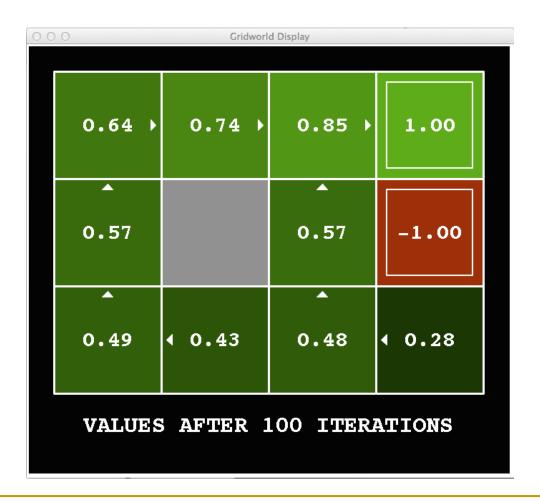

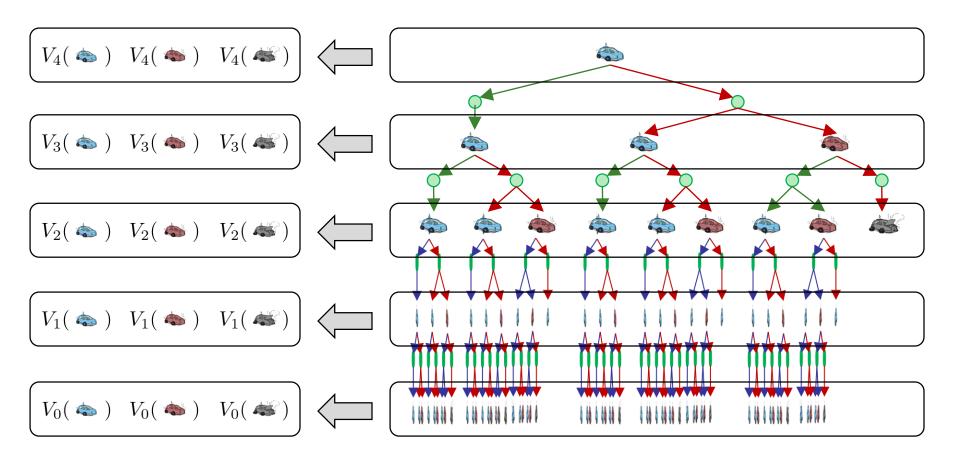

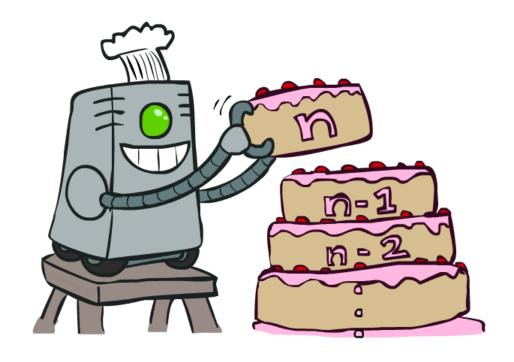

Computing Time-Limited Values

Value Iteration

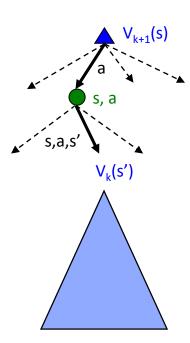

Value Iteration

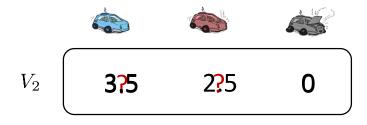

- Start with $V_0(s) = 0$: no time steps left means an expected reward sum of zero
- Given vector of V_k(s) values, do one ply of Expectimax from each state:

$$V_{k+1}(s) \leftarrow \max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V_k(s') \right]$$

- Repeat until convergence
- Complexity of each iteration: O(S²A)
- Theorem: will converge to unique optimal values
 - Basic idea: approximations get refined towards optimal values
 - Policy may converge long before values do

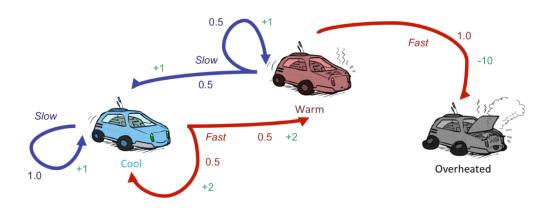

Example: Value Iteration

Assume no discount!

$$V_{k+1}(s) \leftarrow \max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V_k(s') \right]$$

a=slow: $0(5(1 \oplus 2)2) 3 \cdot 0.5(1 + 0) = 2.5$ a=fast: $0(5(2 + 0)) \neq 0(2 + 0) = 2.5$

What we did today

- Working with stochastic environments (but world model known)
- Introduced MDPs (describe problem) and policies (solution)
 - MDPs look similar to expectimax search trees
- Discussed how to solve MDPs
 - Optimal state value V*(s), and q-state value Q*(s,a) are key quantities
 - Bellman equation characterizes the optimal value function:

$$V^*(s) = \max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V^*(s') \right]$$

- A key equation in RL and this class!
- Value iteration is an algorithm to solve the Bellman equation
